2D amorphous iron phosphate nanosheets with high rate capability and ultra-long cycle life for sodium ion batteries†

Tongchao Liu, a Yandong Duan, a Guangxing Zhang, a Maofan Li, a Yancong Feng, a Jiangtao Hu, a Jiaxin Zheng, a Jitao Chen ab and Feng Pan a

In our previous work, we reported the formation and mechanism of mono/bi-layer phosphate-based materials and their high performance as cathode materials for Li-ion batteries. In this work, we report that 2D amorphous nanosheets can be used as cathode materials to achieve outstanding performance for sodium ion batteries (SIBs) e.g. a high initial discharge capacity of 168.9 mA h g⁻¹ at 0.1C, ultra-long life (92.3% capacity retention over 1000 cycles), and high rate capability (77 mA h g⁻¹ at 10C) for Na-ion storage, whose electrochemical performance is also much superior to the reported amorphous FePO₄ or olivine NaFePO₄ with advantages of short paths and larger implantation surface areas for fast Na-ion diffusion and large specific surfaces with more interfacial capacitance. Interestingly, NaFePO₄ nano-crystals with about 10 nm sizes are self-nucleated from amorphous 2D nanosheets in the charge/discharge process, which was verified by transmission electron microscopy (TEM) and in situ electrochemical impedance spectroscopy (EIS).

Introduction

Lithium (Li)-ion batteries (LIBs) are the modern high-performance energy storage devices for portable electronics and increasingly for electrical vehicles due to their high energy and power densities. However, with the increasingly serious energy crisis, the extensive application of LIBs faces important challenges related to both Li availability and cost. Using sodium-ion batteries (SIBs) as an alternative attracted great interest, because Na is more abundant than Li and is easy to recover. In addition, the intercalation chemistry of Na and Li is similar, thus the known LIB knowledge can be exploited in SIB. Nevertheless, many challenges need to be overcome before SIBs can become commercially competitive with LIBs. For instance, compared with lithium, sodium weighs more and has a higher ionization potential and a larger ionic radius, which leads to a lower theoretical capacity and poor rate capacity.

Since the performance of SIBs (e.g. specific capacity and operating voltage) is largely dependent on the electrochemical properties of the electrode materials, it is of great importance to develop suitable electrode materials for SIBs. Among them, phosphate-based materials have been identified as potential electroactive materials for SIBs, such as NaFePO₄ (olivine), NaVOPO₄F, Na₃V₂(PO₄)₂F₃, Na₂(VOPO₄)₂F, Na₃V₂(PO₄)₃, Na₃Al₂(PO₄)₂F₂, Na₃NiPO₄F, Na₂(Fe₃₋ₓCoₓ)PO₄F, Na₂(Fe₁₋ₓMgx)PO₄F, etc. However, crystalline phosphates have so far exhibited poor electrochemical performance for SIBs, because the undersized channel of the lattice limits the diffusion of Na ions. Thus, compared with LIBs, the crystalline phosphate-based sodium cathode materials show poor rate capability and cycling stability, which limits the commercial development of SIBs.

In previous work,1 we reported the formation of a special amorphous mono/bi-layer phosphate-based material and its performance as a cathode material for LIBs, with some natural advantages such as: shorter paths and larger implantation surface areas for fast Li-ion diffusion and large specific surface areas with more interfacial capacitance. When applied in LIBs, it shows excellent performance with high capacity and rate capability. In view of the above natural advantages, such 2D nanosheets should have excellent performance when applied in sodium ion batteries. Herein, we used previous methods to synthesize mono/bi-layer iron phosphate 2D nanosheets to be used as a novel cathode for SIBs, which show excellent performance: a high initial discharge capacity of 168.9 mA h g⁻¹ at 0.1C, ultra-long life (92.3% capacity retention over 1000 cycles), and high rate capability (77 mA h g⁻¹ at 10C) for Na-ion storage. Interestingly, NaFePO₄ nano-crystals are self-nucleated by electrochemical forces driven from the oxidation of amorphous 2D nanosheets during the charge/discharge process.
Experimental

Materials

Atomically thin amorphous 2D-sheets are controllably prepared through a simple chemically induced precipitation method and post-processing, similar to our previous work. The two main fabrication steps are the preparation of the precursor and post-processing by water and ethanol. For the preparation of the precursor, FeSO$_4$$\cdot$7H$_2$O, H$_3$PO$_4$, and LiOH$\cdot$H$_2$O were used as the starting materials. Firstly, 1.05 g FeSO$_4$$\cdot$7H$_2$O was dissolved in 33.30 g of ethylene glycol with nitrogen protection. Secondly, 0.55 g H$_3$PO$_4$ was mixed in 8.80 g of ethylene glycol and then the solution was slowly introduced into the FeSO$_4$ solution under stirring. Thirdly, 0.43 g LiOH was added into 41.6 g of ethylene glycol, dissolved under ultrasonic treatment and then the solution was added into the prior mixed solution, resulting in a dark green precursor. For the post-processing step, the precursor was washed twice with water and once with ethanol. Finally, the product was dried in a vacuum drying oven at 80 °C.

Material characterization

X-ray powder diffraction patterns were collected from a Bruker D8 Advance diffractometer with Cu Kα ($\lambda = 0.15418$ nm) at the 2θ range of 10–80° with a step of 0.02° and a testing time of 1 s. The morphologies were observed by using a SEM (ZEISS Supra 55) and a TEM (FEI Tecnai G2 F20 S-Twin). The energy-dispersive spectroscopy (EDS) was performed by using an Oxford-Max20 detector attached to the SEM. The thickness of nanosheets was measured by using an AFM (Bruker MultiMode 8).

Electrochemical measurements

Electrochemical characterization was performed with 2032 coin cells. For the cathode, FePO$_4$$@$C and PTFE (polytetrafluoroethylene) binder were mixed with isopropanol, in which the weight ratio was 80 : 20. By grinding in an agate mortar, FePO$_4$$@$C and the PTFE binder were mixed evenly, resulting in the cathode plate, and then dried in a vacuum at 110 °C for 12 h. Sodium metal anodes were prepared by cutting and planishing sodium pieces. The 2032 coin cells were assembled with the above cathode plates, sodium metal anodes and electrolytes. All the cells were assembled in a glove box tested at room temperature. The electrochemical characteristics of cells were determined on a NEWARE battery cycler in the voltage range of 1.4–3.8 V (vs. Na$^+$/Na). The cyclic voltammetry (CV) results were obtained by using a CHI 604E (Chenhua Instruments Co., China). The electrochemical impedance spectra were collected from 10$^4$ to 0.1 Hz and the amplitude was 10 mV.

Results and discussion

Fig. 1 shows the morphology of the as-prepared amorphous 2D nanosheets for this work characterized by TEM and AFM, and the schematics of the formed hybrid cathode materials (Fe(II)$_3$(PO$_4$)$_2$.Fe(III)$_3$(PO$_4$)$_2$(OH)$_3$.nH$_2$O/C (“FP@C”) by mixing the 2D nanosheets with carbon black by ball milling. The SEM and TEM images show large scale nanosheets prepared for this work with an average size of more than 1 μm (Fig. S1–S3† and Fig. 1a). High-resolution TEM images clearly illustrate no crystal lattice (Fig. 1b), and the Selected Area Electron Diffraction (SAED) images also show no signals of crystalline diffraction.

FePO₄ nanoparticles mixed with single-wall carbon nanotubes showed cell performance for Na-ion storage. The electrochemical performance shows that the discharge capacity is 120 mA h g⁻¹ at 0.1C rate (10 mA g⁻¹), and the capacity still remains at 50 mA h g⁻¹ after 300 cycles at 1C rate (100 mA g⁻¹). Cao⁴⁰ reported that amorphous FePO₄ nanospheres showed high-performance for sodium ion batteries with a high initial discharging capacity of 151 mA h g⁻¹ at 20 mA g⁻¹, good cycle stability (94% capacity retention ratio over 160 cycles), as well as high rate capability (44 mA h g⁻¹ at 1000 mA g⁻¹). Xu⁴¹ reported that amorphous FePO₄ nanoparticles showed an initial specific discharge capacity of 142 mA h g⁻¹, reversible capacity of 130.8 mA h g⁻¹ after 120 cycles, and high rate capability of 63.5 mA h g⁻¹ at 1C. Liu⁴² reported that FePO₄@MCNT nanowire showed excellent cell performance with a discharge specific capacity of 155.2 mA h g⁻¹ in the initial cycle and 157.2 mA h g⁻¹ after 70 cycles at 0.1C. From Table 1, we can see that our 2D nanosheets show the best electrochemical performance among all reported.

The reasons for the 2D nanosheets to show the remarkable electrochemical performance with high capacity, high rate capacity, and long life can be attributed to the factors given below. Compared with amorphous FePO₄ and olivine NaFePO₄, the 2D nanosheets create shorter paths and larger implantation surface areas for fast Li/Na-ion diffusion. The energy barrier of Na ion insertion of 2D-Na is much lower than that in bulks of olivine NaFePO₄. Because of the larger ionic radius, Na ions are difficult to insert into undersized channels of bulks of olivine NaFePO₄. For 2D nanosheets, the diffusion of sodium ions is not limited in mono/bi-layer materials. Another reason is that the large surfaces of the 2D nanosheets would contribute large interfacial capacitance to the total capacity. Similar to 2D nanosheets in lithium ion batteries, to investigate the effect of the capacitance-type behavior of 2D nanosheets on their electrochemical performance, we measured a series of CV curves at scan rates of 0.1–0.5 mV s⁻¹. The shapes of these CV curves (Fig. 2d) show no distortion with the speeding up of the scanning rate, meaning that the 2D nanosheets exhibit an excellent rate capability. Assuming that the current and the scan rate follow a power-law relationship,⁴³ \( I_p = aV^b \), where \( a \) and \( b \) are adjustable values. The \( b \) value of 0.5 indicates that the current is controlled by semi-infinite linear diffusion, while the \( b \) value of 1 indicates that the current is surface-controlled like capacitance.⁴⁴ The \( b \)-values obtained in the range of 1.8–3.6 V are between 0.503 and 0.838, indicating a concurrence of both sodium ion semi-infinite linear diffusion and surface-controlled pseudocapacitance (Fig. 2e). We further investigated the capacitance contribution to the sodium ion battery capacity, as shown in Fig. 2f. According to CV curves, the electric quantity of the whole cycle and the capacitance part were calculated separately by numerical integration. The results show that the capacitive contribution in the sodium ion battery is almost unchanged at any scan rate, and interfacial capacitance accounted for 31.7–33.8% of the total capacity, as shown in Fig. S7.†

We further compared the electrochemical performance of 2D nanosheet SIBs (2D-Na) with that of 2D nanosheets LIBs (2D-Li). As shown in Fig. 3a, the average voltage of the discharge curve of 2D-Na is lower than that of 2D-Li by 0.31 V, which is smaller than the voltage reduction of 0.53 V from olivine LiFePO₄ to NaFePO₄.⁴² In addition, compared with bulk crystalline materials, the variation of the rate capability between 2D-Li and 2D-Na is much smaller (Fig. 3b). For example, the capacity of bulk olivine NaFePO₄ is decreased from 120 mA h g⁻¹ @ 0.1C to 40 mA h g⁻¹ @ 2C, 2.5 times larger than the capacity decrease for olivine LiFePO₄ (168 mA h g⁻¹ @ 0.1C vs. 120 mA h g⁻¹ @ 2C). In contrast, the capacity of 2D-Na is decreased from 169 mA h g⁻¹ @ 0.1C to 77 mA h g⁻¹ @ 10C, 1.5 times larger than the capacity decrease for 2D-Li (185 mA h g⁻¹ @ 0.1C and 127 mA h g⁻¹ @ 10C for 2D-Li). The much better rate capability performance of 2D-Na is due to the absence of undersized channels for diffusion. We further compared the resistance of 2D-Li and 2D-Na (Fig. 3c), and the data are analyzed according to the following equation:⁴³

\[
D_{Li^+} = R^2T^2/2A^4n^4F^4C^2\kappa^2
\]

where \( R \) is the gas constant, \( T \) is the absolute temperature, \( A \) is the surface area of the electrode, \( n \) is the number of electrons per molecule, \( F \) is the Faraday constant, \( C \) is the concentration of Li-ions, and \( \kappa \) is the Warburg factor to be determined from the slope of the low frequency part of resistance. It can be seen that 2D-Li and 2D-Na have a similar \( \kappa \), so the diffusion coefficients of those are similar, which further indicates 2D nanosheets with shorter diffusion paths for cation storage.

Electrochemical impedance spectroscopy (EIS) is used to study the electrode reaction kinetics of 2D-Na. We tested the EIS of the coin cell after 1, 10, 20, 40, and 100 cycles at 1C as shown in Fig. 4a and Fig. S8,† in which the visible semicircles in the high and middle frequency ranges reflect the solid-electrolyte interface (SEI) resistance (\( R_{SEI} \)) and charge transfer resistance (\( R_{ct} \)), respectively. Similar to ref. 1, the third semicircle appears in the low frequency ranges with charge/discharge cycles, which indicates that additional diffusion behavior appears in semi-

Fig. 3 (a) Discharge curve of 2D-Na and 2D-Li. (b) Rate capability of 2D-Li, 2D-Na, LiFePO₄ and NaFePO₄. (c) Electrochemical impedance spectroscopy (EIS) of 2D-Li and 2D-Na. (d) The image of an LED lit by a 2D nanosheet sodium ion battery.
infinite linear diffusion. We speculate that the additional diffusion behavior is associated with the formation of NaFePO₄ nano-crystalline particles as the new “second-phase” (see Fig. 4c and d). The “transmission line” model is proposed to explain the special EIS features. Due to the presence of amorphous and crystal phases in the 2D nanosheets, the Na⁺ can diffuse into/from the amorphous phase and NaFePO₄ nano-crystalline particles during the discharge/charge process, which leads to two kinds of diffusion behavior and the second semicircle.

To further validate the second phase generated after cycling, we dismantled the coin cell after 1000 cycles at 1C and cleaned the electrode materials for EDS, XRD and TEM analyses. The EDS mapping (Fig. S9†) shows Na ion insertion into the 2D nanosheets. Fig. 4b shows the XRD patterns of the electrode materials with strong reflection peaks at 28.2 and 41.4, which correspond to the phase structure of (020) and (212) planes of crystalline NaFePO₄, respectively. The TEM (Fig. S10† and Fig. 4c) images show that the morphology of 2D nanosheets remains unchanged and many nano-crystal particles with 10–15 nm sizes are inside the 2D nanosheets. Furthermore, the high magnification TEM images (Fig. 4d and Fig. S11†) revealed the obvious lattice channels in the nano-particles with two inter-planar distances of about 0.22 nm and 0.32 nm. This finding is consistent with the d_{221} value (0.22 nm) and the d_{020} value (0.32 nm), calculated from the XRD pattern of olivine NaFePO₄ crystals. Thus, both TEM and XRD results strongly proves that olivine NaFePO₄ nano-crystals can be nucleated and grown from atomically thin amorphous 2D nanosheets in the electrochemical charge/discharge cycles. The nucleation of NaFePO₄ nano-crystals (limited sizes about 10–15 nm) from amorphous matrix is interesting. Its mechanism can be proposed that NaFePO₄-like short-ordering structures in the amorphous 2D nanosheets can become nucleation-centers, but it is hard to grow a nucleus of big size because of the high mobility resistance of the iron phosphate group in the solid amorphous phase. The ratio of NaFePO₄ nano-crystalline part to amorphous part is difficult to be defined.

Conclusions

We used the synthesized mono/bi-layer amorphous iron phosphate nanosheets milled with carbon black to generate hybrid cathode materials for SIBs, which show a high reversible capacity of 168.9 mA h g⁻¹ @ 0.1C, high rate capability of 77 mA h g⁻¹ @ 10C, and an excellent cycling stability with 92.3% capacity retention after 1000 cycles. This electrochemical performance is also superior to the reported high performance of SIBs based on amorphous FePO₄ or olivine NaFePO₄. The high performance can be attributed to the shorter paths and larger implantation surface areas for fast Na-ion diffusion and more interfacial capacitance in such mono/bi-layer amorphous ion phosphate nanosheets. Interestingly, self-nucleated NaFePO₄ nano-crystals with sizes of about 10–15 nm as the new phase can be in situ observed by EIS during the electrochemical charge/discharge cycles. This work reveals that the atomically thin 2D nanosheets can become novel electrode materials with the hybrid behavior of batteries and supercapacitors for high-performance sodium ion batteries.
